Abstract

In this study, ionic liquid 1-hexyl-3-methylimidazolium hexafluorophosphate was applied as additives to fabricate a novel ionic liquid/carbon nanotube paste electrode (IL/CNPE). This electrode was characterized by electrochemical impedance spectroscopy and cyclic voltammetry. Results showed that the electron transfer rate and reversibility of the electrode were increased by the ionic liquid. The morphology of prepared IL/CNPE was studied by scanning electron microscopy. Nickel/ionic liquid modified carbon nanotube paste electrode (Ni/IL/CNPE) was also constructed by immersion of the IL/CNPE in nickel sulfate solution. Ionic liquid showed significant effect on the accumulation of nickel species on the surface of the electrode. Also, the values of electron transfer coefficient, charge-transfer rate constant and electrode surface coverage for Ni(II)/Ni(III) redox couple of the Ni/IL/CNPE were found to be 0.32 and 2.37×10⁻¹ s⁻¹ and 2.74×10⁻⁸ mol.cm⁻², respectively. The Ni/IL/CNPE was applied successfully to highly efficient electrocatalytic oxidation of formaldehyde in alkaline medium. The effects of various factors on the efficiency of electrocatalytic oxidation of formaldehyde were optimized. Under the optimized condition, cyclic voltammetry of formaldehyde at the modified electrode exhibited two linear dynamic ranges in the concentration ranges of 7.00×10⁻⁶ to 9.60×10⁻⁵ mol.L⁻¹ and 9.60×10⁻⁵ to 32.00×10⁻³ mol.L⁻¹ with excellent detection limit of 9.50×10⁻⁷ mol.L⁻¹ (3σ/slope), respectively. Also, the method was successfully applied for formaldehyde measurement in real sample. Copyright © 2018 BCREC Group. All rights reserved

1. Introduction

Formaldehyde is one of the toxic pollutants (as a carcinogen) [1]. Also, this material was applied as an extremely important industrial raw material for the production of phenol-, urea-, and melamine-formaldehyde resins and manufacturing of building plates, plywood, and lacquer materials [2,3]. Formaldehyde is also used in chemical synthesis as an intermediate for the production of consumer goods as detergents, soaps, shampoos, and as a sterilizing agent in
pharmacology and medicine. On the other hand, formaldehyde is a natural metabolite of living organisms. It can be found in fruits, vegetables, flesh [4] and biological fluids of human origin [2]. Therefore, simple and sensitive methods for determination of formaldehyde are needed for specific biotechnological processes, environmental control, medicine and even for drinking water and food analysis. Compared with spectral and chromatographic analysis, electroanalytical method has been considered as a good alternative for formaldehyde detection due to its high sensitivity, selectivity and its potential for providing real-time measurements.

Achmann et al. [5] studied on the sensor electrode with multi walled carbon nanotube films modified with graft percentage of amine-groups modified electrode to detect the concentration of formaldehyde. The result illustrated that the sensor displayed high chemical selectivity, fast response and good reproducibility to low concentration formaldehyde. Amperometric sensors in the potentiostatic mode using noble metals as electrode nanomaterials are also used for formaldehyde detection [6]. Metal nanomaterials have high effective surface areas and extraordinary electron-transport properties. Their using as electrochemical interface provides a rapid current response and high-detection sensitivity. Consequently, the electron transfer between the electrode and the probe molecules is accelerated. Zhang et al. [7] introduced the electrodeposition of a nanostructured palladium in aluminum oxide membrane coated glassy carbon electrode. The proposed sensor not only possesses a broad linear range, good reproducibility and high sensitivity, but also exhibits a synergistic effect that minimizes poison formation. Yi et al. [8] reported a novel formaldehyde detection method based on nanoporous palladium modified TiO2 electrode in alkaline solutions.

Ionic liquids are stable salts, composed of an organic cation and an organic or inorganic anion, and preserved in liquid state over a wide temperature range [9-11]. In the past few years, ionic liquids have emerged as a frontier and novel area of research because of their excellent chemical and physical properties, such as: good solvating properties, high chemical and thermal stability, non-flammability, low toxicity, almost negligible vapor pressure, high conductivity, and wide electrochemical window [12-14]. As green solvents, ionic liquids has been proposed to be very interesting and efficient pasting binders in place of non-conductive organic binders for the preparation of carbon composite electrodes [15,16]. Using ionic liquid as a pasting binder, it can be constructed a new generation of carbon composite electrodes with advantages over carbon paste electrodes, such as: high conductivity, fast electron transfer rates, and antifouling properties [17].

There are various known hydrophobic ionic liquids that can be used as binders for construction of these classes of electrodes. These ionic liquids mainly consist of bis (trifluoromethylsulfonyl)imide or hexafluorophosphate anions. On the other hand, several studies showed that carbon nanotubes present strong electrocatalytic activity for a wide range of different materials such as 6-thioguanine [18], epinephrine [19], glutathione [20], dopamine and uric acid [21], ascorbic acid [22], and cytochrome c [23]. Most of the carbon nanotube-based electrodes for electroanalytical applications are based on physical adsorption of carbon nanotubes onto electrode surfaces, usually glassy carbon [24]. However, it is important to note that carbon nanotubes dispersed in mineral oil [18-20] or consolidated into Teflon [25] have been recently used. Ensafi et al. [26] have applied multiwall carbon nanotubes-ionic liquid paste electrode for determination of iso-proterenol.

In respect of literature survey, no ionic liquid 1-hexyl-3-methylimidazolium hexafluorophosphate modified carbon nanotube paste electrode was employed towards electrocatalytic oxidation of formaldehyde. The aim of this work presented here is to develop a 1-hexyl-3-methylimidazolium hexafluorophosphate modified carbon nanotube paste electrode to form complex with Ni2+, which provided a simple, sensitive, rapid and low-cost sensor for electrocatalytic oxidation of formaldehyde in the alkaline medium.

2. Materials and Methods

2.1 Materials

Multiwalled carbon nanotubes (MWCNTs) (diameter: 30±15 nm, 95 % purity and length: 5-20 μm) was purchased from Aldrich. Graphite powder and high-purity paraffin oil from Fluka were used for fabrication the carbon paste electrode (CPE). Sodium hydroxide, formaldehyde, NiCl2·6H2O and potassium hexacyanoferrate (K3[Fe(CN)6]) were purchased from Merck company that were of analytical reagent grade. The 1-hexyl-3-methylimidazolium hexafluorophosphate was from Aldrich. All materials were used without any further
purification. Also, all solutions were prepared with double distilled water. All solutions were freshly prepared with double distilled water. All other reagents were of analytical grade. The solvent used in this study was twice distilled water.

2.2 Preparation of Working Electrodes

The IL/CNPE was prepared by thoroughly mixing 1.0 g of carbon nanotube powder with 0.25 g of paraffin oil and about 1.0 g of ionic liquid in a mortar to form a homogeneous carbon nanotube paste. A portion of the carbon nanotube paste was filled firmly into one end of a glass tube (internal radius 3 mm), and a copper wire was inserted through the opposite end to establish an electrical contact. The surface of the IL/CNPE was polished on a piece of weighing paper to obtain a smooth surface just before use. The bare CPE and CNPE were fabricated according to same procedure, with adding paraffin oil (0.50 g) to graphite (1.0 g) and carbon nanotube (1.0 g) powders respectively, for comparison purpose.

2.3 Instrumentation

Voltammetric measurements were performed at a Metrohm Computrace Voltammetric Analyzer Model 797 VA with a conventional three-electrode cell. The bare CPE, bare CNPE, ionic liquid modified carbon nanotube paste electrode (IL/CNPE) and nickel/ionic liquid modified carbon nanotube paste electrode (Ni/IL/CNPE) were used as working electrodes. Also, the auxiliary electrode was a platinum rode, and an Ag|AgCl/KCl (3 M) was applied as a reference electrode. During the measurements, the solution in the cell was neither stirred nor aerated. Measurements of pH were made with a Denver Instrument Model 827 pH meter equipped with a Metrohm glass electrode. Scanning electron microscopy (SEM) (Philips Corp., XL30 model) was used for seeing of the surface morphology of the modified electrodes.

2.4. Sample Analysis

100 μL of formalin were diluted in 10 mL of water and then, an aliquot (400 μL) was added to 25 mL of 0.1 M NaOH solution and recorded by cyclic voltammetry under optimized experimental conditions. The concentration of formaldehyde was measured from calibration curve. All experiments were performed in triplicate.

3. Results and Discussion

3.1 Characterization of the IL/CNPE

Potassium ferrocyanide was chosen as a probe to evaluate the performance of the proposed electrodes. Figure 1 illustrates the cyclic voltammograms of the electrochemical oxidation of K₄Fe(CN)₆ at the surface of the bare CPE, bare CNPE and IL/CNPE in the 27.00 mM of K₄Fe(CN)₆ solution. As can be seen in Figure 1, the anodic and cathodic peak currents for the bare CNPE is higher than that at the bare CPE and peak currents for the IL/CNPE is greater than that of the bare CNPE. The experimental results show reproducible anodic and cathodic peaks ascribed to Fe(CN)₆³⁻/Fe(CN)₆⁴⁻ redox couple at slow scan rates at the surface of IL/CNPE. This is a quasi-reversible system because the peak separation potential, ΔEₚ (Eₚa−Eₚc), is equal to 288.1 mV (349-80.9) and is greater than 59 mV that expected for a reversible system. The ΔEₚ of Fe(CN)₆³⁻/Fe(CN)₆⁴⁻ redox couple at the surface of the bare CPE was obtained to be 430 mV (as a quasi-reversible system) [27] and is greater than that at the bare CNPE and IL/CNPE.

Electrochemical impedance spectroscopy was widely applied to characterize the interface properties of the electrode [28]. Electrochemical impedance spectroscopy was em-

![Figure 1. The cyclic voltammograms of 27.00 mM K₄Fe(CN)₆ at the surface of (a) bare CPE, (b) bare CNPE and (c) IL/CNPE in the phosphate buffer solution (pH 7.0) at a scan rate of 20 mV.s⁻¹](image)
ployed in order to discriminate between the unmodified and modified electrodes. Figure 2 showed the typical Nyquist plots for the unmodified CNPE (a) and IL/CNPE (b) in phosphate buffer solution (pH 7.0) consisting of redox probe \([\text{Fe(CN)}_6]^{3/4-}/4^-\) \((2.0\times10^{-3}\text{M})\). It is clear, considerable differences in the electrochemical impedance spectroscopy were observed for these two electrodes.

The unmodified CPE presented a large semicircle in the high frequencies range with a large resistance of electron transference, showing a low electrochemical activity of \([\text{Fe(CN)}_6]^{3/4-}\) on the unmodified CPE. This may be due to the presence of oil as an insulating material, which decreases the electron transfer rate of the \([\text{Fe(CN)}_6]^{3/4-}\) redox couple at the electrode surfaces. Notwithstanding, the IL/CNPE showed a quasi-semicircle section of much smaller diameter in the high frequencies range, which was related to the suitable ionic conductivity of ionic liquid and the lower resistance to electron transfer of the IL/CNPE. The obtained results about the IL/CNPE exhibited that the Nyquist plot is a straight line with a larger slope compared to the unmodified CNPE, at low frequencies, which is related to a diffusion-limited electrochemical process. Based on the results, it was proved that the IL/CNPE could successfully increase the electron transference rate of \([\text{Fe(CN)}_6]^{3/4-}\) and obtained very varied features from those of the unmodified CNPE.

3.2 Surface Morphology of the IL/CNPE

The surface morphology of the fabricated electrodes was characterized by SEM. Figure 3 shows the SEM images of (a) MWCNTs and (b) IL/CNPE. In the absence of ionic liquid, the MWCNTs are heavily entangled, forming a typical agglomerative structure. However, the SEM recorded for the MWCNTs in the presence of ionic liquid (Figure 3b) shows the formation of a material with gel aspect with MWCNTs wrapped by the ionic liquid architecture. The ionic liquid reduces the agglomeration of the nanotubes, which were more dispersed.

3.3 Incorporation of Ni(II) Ions into the Electrode

Figure 4 illustrates the (a) Ni/CNPE and (b) Ni/IL/CNPE in 0.1 M NaOH solution at the potential range from 0.10 to 0.75 V vs. Ag|AgCl|KCl (3 M) and potential sweep rate of 10 mV.s\(^{-1}\). In order to incorporate Ni(II) ions into the surface of the electrode, the freshly prepared electrode was placed in a well stirred aqueous solution of 0.5 M NiSO\(_4\) at an open circuit for 5 min (accumulation time, 5 min). Afterward, the electrode was transferred into a cell containing 0.1 M NaOH solution, and potential cycling was performed. It can be de-
duced that the electrochemical behaviour of Ni/CNPE and Ni/IL/CNPE as modified electrodes in alkaline solution is similar to that of Ni anode [29]. These redox waves are ascribed to the formation of Ni(OH)$_2$ and then its oxidation at the electrode surface to NiOOH and reduction of NiOOH to Ni(OH)$_2$ with a peak potential of 427 and 267 mV vs. Ag|AgCl|KCl (3 M), respectively (Eqs. 1 and 2) [30]:

$$\text{Ni}^{2+} + 2\text{OH}^- \rightarrow \text{Ni(OH)}_2 \quad (1)$$

$$\text{Ni(OH)}_2 + \text{OH}^- \rightleftharpoons \text{NiOOH} + \text{H}_2\text{O} + \text{e}^- \quad (2)$$

By comparing Figure 4(a) and (b), it can be indicated that the presence of ionic liquid in the electrode construction performed a significant effect to accumulation of nickel species on the surface of electrode. Because, ionic liquid greatly increase the effective surface area and consequently, enhance the electron transfer rate between the electrode surface and Ni(OH)$_2$ [31]. The shoulders in the cathodic peak of Figure 4(b) can be attributed to different crystalllographic forms of Ni(OH)$_2$ ($\alpha$ and $\beta$ phases), as previously reported in other articles [32].

Several working groups have studied the extraction behaviour of “classical” hydrophobic room temperature ionic liquids based on imidazolium cations for different metals (e.g. alkali metals, Co, Ni, Zn, Mn) from aqueous solutions [33]. The X-ray photoelectron spectroscopy (XPS) analyses proved that the interaction between the metal surface and the IL occurs through F, when the anion is $[\text{BF}_4]^-$ of $[\text{PF}_6]^-$ or through O with the triflate, $[\text{CF}_3\text{SO}_3]$ anion [34]. Consequently, one would assume that the ionic multilayer is composed of anions located immediately adjacent to the nanoparticle surface (Figure 5) [34,35]. Also, imidazolium cations through their imidazolium -C–H groups can form hydrogen bonds to the fluorine or oxygen atoms of the IL anions [34,35]. Metal nanoparticles can possess hydroxido and/or oxido ligands on their surface, which can also hydrogen bond with ionic liquids [34]. The IL cation-anion hydrogen bond and metal nanoparticle hydrogen bond compete with each other and contribute to metal nanoparticle stabilization in ionic liquids, as shown in Figure 6.

3.4 Electrocatalytic Oxidation of Formaldehyde at the Ni/IL/CNPE

In this work, the oxidation of formaldehyde was studied at the surface of Ni/IL/CNPE by cyclic voltammetric experiments in 0.1 M NaOH solution. Typical results obtained for a potential range from 0.10 to 0.75 V vs. Ag|AgCl|KCl (3 M) at the potential scan rate of 10 mV.s$^{-1}$ were shown in the Figure 7. For comparison, cyclic voltammograms IL/CNPE was illustrated in 0.1 M NaOH solution containing 30.00 mM formaldehyde (Figure 7(a)). Comparison of curves (a), (b) and (c) in Figure 7 shows that in the presence of formaldehyde, an increase in current was observed at the surface of Ni/IL/CNPE (Figure 7(c)). It can be demonstrated that the oxidation of formalde-
hyde gives rise to a typical electrocatalytic response, with an increase in the anodic peak current and a decrease in the cathodic peak current. The oxidation potential of Ni(OH)$_2$ in the presence of formaldehyde is observed at ca. 624 mV that is positive than the potential observed for Ni$^{2+}$ to Ni$^{3+}$ transition at the surface of Ni/IL/CNPE in the absence of formaldehyde (i.e. 427 mV).

It can be specified that the formaldehyde molecule is completely hydrated and converted to the methylene glycol (CH$_2$(OH)$_2$) with an equilibrium constant on the order of 10$^3$ in aqueous solution [36]. The methylene glycol exists predominantly in its ionized form (CH$_2$(OH)O) in 0.1 M NaOH solution due to its pK$_a$ of ca. 12.8. When CH$_2$(OH)O$^-$ diffuses from the bulk solution to the electrode surface and is quickly oxidized to CH$_2$(O)O$^-$ by the NiOOH species on the surface of Ni/IL/CNPE. Therefore, the amount of NiOOH species decreases due to its chemical reaction with CH$_2$(OH)O$^-$.

The overall reaction, formaldehyde can be converted to the CH$_2$(O)O$^-$ and generated one electron (see Figure 8) [37]. Simply, this behaviour is a typical observation expected from the mediated oxidation (EC′ mechanism), illustrated in the following equations:

$$\text{Ni(OH)}_2 + \text{OH}^- \rightleftharpoons \text{NiOOH} + \text{H}_2\text{O} + e^- \quad E \quad (2)$$

$$\text{NiOOH} + \text{CH}_2(\text{OH})\text{O} \rightarrow \text{Ni(OH)}_2 + \text{CH}_2(\text{O})\text{O}^- \quad C' \quad (3)$$

Figure 7. The cyclic voltammograms of (a) IL/CNPE, (b) Ni/IL/CNPE in 0.1 M NaOH and (c) Ni/IL/CNPE in 0.1 M NaOH containing 30.00 mM formaldehyde at a scan rate of 10 mV.s$^{-1}$

![Figure 7](image)

The electrochemical behaviour of Ni/IL/CNPE was investigated in 0.1 M NaOH at various scan rates. Figure 9A shows the cyclic voltammograms of Ni/IL/CNPE in 0.1 M NaOH solution at different potential sweep rates. As can be seen, the anodic and cathodic currents were enhanced with increasing of scan rate and a potential moved to positive values. The positive shift may be due to the kinetic limitation in diffusion layer which created at high current density. The $\Delta E_p$ was increased with scan rate that indicated a limitation in the charge transfer kinetics. Obviously, the anodic and cathodic peak currents are linearly proportional to the potential sweep rate at low values from 10 to 50 mV.s$^{-1}$ (Figure 9B). The electrode surface coverage ($I^*$) can be calculated from the linear part of the plot and using the following equation which correspond to reversible process with adsorbed species [38].

$$I_p = (n^2F^2/4RT)\nu A \Gamma^*$$

where, $I_p$, $n$, $\Gamma^*$, and $A$ are the peak current, the number of electrons involved in the reaction ($n = 1$), the surface coverage of the redox species and the surface area of the electrode (0.28 cm$^2$), respectively. The total surface coverage of the immobilized active species [Ni(II)] is found to be about 2.74×10$^{-8}$ mol.cm$^{-2}$, considering the mean of both anodic and cathodic currents. At scan rates larger than 75 mV.s$^{-1}$, both the anodic and cathodic peak currents depend on root mean square of scan rate ($\nu^{1/2}$) that express a diffusion controlled process dominates with increasing the scan rates (see Figure 9C). This limiting-diffusion process can be related to the charge neutralization of the electrode surface during the oxidation/reduction process [39].

The effect of $\nu$ on peak potential was also investigated by voltammetry. With the increase
of $\nu$, the oxidation peak potential is positively shifted, and the reduction peak potential is negatively shifted, indicating that the redox reversibility of nickel oxide film was impaired. Under the surface controlled redox process, the electron transfer kinetics of nickel oxide film on the surface of the Ni/IL/CNPE can be obtained by using the approach developed by Laviron [40]; when peak to peak separation is higher than 200 mV/n, the relationship between the peak potential, $E_p$, and the scan rate can be expressed in Eq. 4:

$$E_p = f(\log \nu)$$

(5)

Figure 9D provided the variations of peak potentials with the logarithm of the scan rate in the ranges of 10-500 mV s$^{-1}$ for both anodic and cathodic peaks that data extracted from cyclic voltammograms of the Ni/IL/CNPE in 0.1 M NaOH solution. It can be observed that $E_p$ is proportional to $\log \nu$ at $\nu > 50$ mV s$^{-1}$. From the slope of the oblique asymptotes, where for cathodic peak, the slope value is $-2.3RT/\alpha n F$, and for anodic peak, $2.3RT(1-\alpha) nF$, the electron transfer coefficient ($\alpha$) of nickel oxide film was calculated. Furthermore, the standard rate constant of reaction, $k_s$, is expressed in Eq. 5 [40]:

$$\log k_s = \alpha \log(1-\alpha) + (1-\alpha) \log(\nu) - \frac{\alpha(1-\alpha) n F \Delta E_p}{2.3RT}$$

(6)

where, $\Delta E_p$ is the peak to peak potential separation. The resulting values of $\alpha$ and $k_s$ were obtained 0.32 and $2.37 \times 10^{-1}$ cm.s$^{-1}$, respectively. Figure 10A displays the cyclic voltammograms of Ni/IL/CNPE in 0.1 M NaOH solution.
containing 4.0 mM formaldehyde at different potential sweep rates. Also, Figure 8B presents a plot of scan rate normalized current ($I_{pa}/\sqrt{\nu}$) vs logarithm scan rate (log $\nu$) obtained based on data of Figure 10A. Figure 10B appears the characteristic shape of an EC' process which express that the electrode reaction is coupled with an irreversible follow up chemical step [41,42].

Comparison of the various parameters obtained here in our study with the literatures can be given to further evaluate the present electrode, Ni/IL/CNPE. Table 1 lists the values of the anodic peak potential, $E_{pa}$ and the current density, $I$, of the formaldehyde electro-chemical oxidation and the formaldehyde concentration used to generate the corresponding current density [43-48]. As can be seen from the Table, it seems clearly that nickel hydroxide in the Ni/IL/CNPE can act as a comparable catalyst in the oxidation of formaldehyde and the obtained values here in this work are better than in many cases and comparable with others. Besides, the surface modification of the electrode is simple and reproducible compared that some modified electrodes and this novel catalyst can be utilized in fuel cell system.

Table 1. Comparison of the electrocatalytic behavior of Ni/IL/CNPE for oxidation of formaldehyde with some of the previously reported electrodes.
3.5 Effect of Experimental Parameters on the Ni/IL/CNPE Performance

3.5.1 Effect of accumulation time

In order to study this factor, voltammetric responses of the Ni/IL/CNPE at the three different accumulation times 1.0, 1.5, and 5.0 min were performed by cyclic voltammetry technique at 0.1 M NaOH solution containing 30.00 mM formaldehyde. The value of $\Delta I_p$ increased gradually with increasing of accumulation times. The maximum value was got at 1.0 min then decreased, so 1.0 min was chosen as the optimum time, which indicated that probably surface active sites of modified electrode get saturated at 1.0 min and at the other times, this may be due to the fact that based on Eq. 1, the excess amount of Ni(OH)$_2$ present on the electrode surface, the electrode conductivity decreases (Figure 11).

3.5.2 Effect of Ni$^{2+}$ ions concentration

The effect of the amount of nickel on response of the Ni/IL/CNPE was studied at accumulation time 1.0 min by varying the concentration of nickel chloride (0.25, 0.50, 1.0, and 1.5 M) in the deposition bath in 0.1 M NaOH solution containing 30.00 mM formaldehyde. It was observed that as the concentration of Ni in the bath increased, the formaldehyde oxidation currents also increased up to 0.5 M; after which, it decreased (Figure 12). According to Eq. 1, it may be due to the excessive presence of Ni(OH)$_2$ on the modified electrode surface reduces the electrode conductivity.

3.5.3 Effect of NaOH concentration

For this purpose, the experiments were carried out with the Ni/IL/CNPE in different NaOH solutions (0.01, 0.1 and 1.0 M). The values of $\Delta I_p$ were measured from the cyclic voltammograms of Ni(OH)$_2$/NiOOH oxidation the absence and presence of formaldehyde that higher anodic current difference was obtained in 0.1 M NaOH (Figure 13). It is suggested that at low concentration of NaOH, the formed amount of Ni(OH)$_2$ is low in the surface of modified electrode. Also, with increasing NaOH, over than 0.1 M, the anodic peak currents difference of the Ni/IL/CNPE in the absence and presence of formaldehyde decreases. It may be due to the electrode conductivity decreases by the excessive presence of Ni(OH)$_2$ on the electrode surface.

3.6 Calibration Curve

The cyclic voltammograms were recorded for calibration graph construction on the Ni/IL/CNPE under the optimum conditions described above using standard addition method as presented in Figure 14A. Under all the optimized experiment conditions, the anodic peak current obtained from cyclic voltammograms of formaldehyde on the Ni/IL/CNPE was proportional to the concentration of formaldehyde in two concentration ranges of $7.00 \times 10^{-6}$ to $9.60 \times 10^{-5}$ mol.L$^{-1}$ (Figure 14B) and $9.60 \times 10^{-5}$ to $32.00 \times 10^{-3}$ mol.L$^{-1}$ (Figure 14C), respectively. The proposed method presented an excellent detection limit of $9.50 \times 10^{-7}$ mol.L$^{-1}$.

![Figure 11](image1.png)  
**Figure 11.** Effect of accumulation time on difference between anodic peak currents ($\Delta I_{pa}$) of the Ni/IL/CNPE (immersed in 0.5 M NiCl$_2$ solution) in the absence and the presence of 30.00 mM formaldehyde in 0.1 M NaOH at scan rate of 10 mV.s$^{-1}$

![Figure 12](image2.png)  
**Figure 12.** Effect of nickel concentration on difference between anodic peak currents ($\Delta I_{pa}$) of the Ni/IL/CNPE (accumulation time 1.0 min) in the absence and the presence of 30.00 mM formaldehyde in 0.1 M NaOH at scan rate of 10 mV.s$^{-1}$
(3σ/slope). Since the acceptable detection limit according to the standards of Occupational Safety and Health Administration (OSHA), varies from 0.1 to 1 mM formaldehyde [20], therefore, this sensor offers very low detection limit the quantification of formaldehyde. Also, the simplicity of the electrode preparation is a main advantage of this method for determination of formaldehyde. The comparison of several parameters of formaldehyde at some modified electrodes is listed in Table 2. It can be seen from the table that the detection limit and linear range obtained in this study are comparable with values reported by other research groups for the electrocatalytic oxidation of formaldehyde.

3.7 Repeatability and Stability of the Ni/IL/CNPE

To evaluation and confirmation the repeatability of Ni/IL/CNPE, five repeatedly cyclic voltammetry was performed under the optimized conditions. The anodic peak currents of Ni/IL/CNPE to electrocatalytic oxidation of 30.00 mM formaldehyde were tested and the relative standard deviation (RSD) was 6.8% for five measurements. This result showed that the repeatability of the electrode is suitable. The stability of the electrode was estimated using monitoring of the electrode response to electrocatalytic oxidation of 30.00 mM formaldehyde after being stored at room temperature for 15 days. It was observed that, the current response preserved almost 91% of its initial amounts.

3.8 Real Sample Analysis

In order to demonstrate the capability of the Ni/IL/CNPE toward determination of formaldehyde in a real sample, this modified electrode was used in voltammetric determination of formaldehyde in formalin. The determination of formaldehyde was carried out by the standard addition method. The data obtained for analysis formaldehyde by this method have been illustrated for several times in Table 3. Also, in order to investigate the proposed method the same sample was analyzed using sodium sulfate titration method in acidic solution as an official method [53]. The results have been summarized in Table 3. As it can be seen, the re:
results obtained from the two methods are in good agreement and confirm the reliability of the proposed method. A statistical test ($F$-test) was used to confirm the precision of the proposed method. As it can be seen, $F$-test results bear a noticeable difference from the critical value (19.00 in four degrees of freedom and 95% of confidence). Moreover, a statistical $t$-test was performed to evaluate the accuracy of the proposed method. The results suggested that there is no evidence of systematic difference between the results obtained by either of the methods. Four degrees of freedom and 95% of confidence as well as the critical $t$-value (2.78) were used to support the conclusions of this test.

4. Conclusions

In this paper, it was firstly described, that ionic liquid 1-hexyl-3-methylimidazolium hexafluorophosphate has been used for bulk modified CNPE fabrication (IL/CNPE). Characterization results of the IL/CNPE using electrochemical impedance spectroscopy and cyclic voltammetry showed that the ionic liquid increases the electron transfer rate and reversibility of the electrode. Also, scanning electron microscopy was used for investigation of the surface morphology of IL/CNPE. On the other hand, the prepared Ni/IL/CNPE by immersion of the IL/CNPE into NiCl$_2$ solution, presented reasonable catalytic performance for the electrocatalytic oxidation of formaldehyde. Electrocatalysis of formaldehyde oxidation is sensitive to various parameters such as accumulation time, nickel amount and NaOH concentration. This new and simple sensor showed promising determination of formaldehyde with excellent detection limit and comparable with values reported by other research groups. The Ni/IL/CNPE can be successfully used as a voltammetric sensor for formaldehyde determination in real sample with suitable precision and accuracy.
