Abstract

A pilot – level system of the termal pirolisis process was developed to obtain biocarbon with minimal emission of polluting gases, from the solid waste generated in the pruning gases, from the solid waste generated in the pruning and gardening of the university campus of the University of Santander in Bucaramanga Colombia. The pilot – level system has a processing capacity of 50 kilograms of pruning and garden waste, and the operating variables ser 500ºC of temperatura and 120 minutes of processing. The prunign and gardenning samples were divided into two. The first simple consisted of Woody-type residues (pruningn), the second simple consisted of grass and leat litter remains. The biocarbons obtaneid were characterizied physicochemically, by close analysis and last chemical analysis (CHN). For its part, the morphology of the biocarbons and the microchemical anlysis of the ash particles that they possessed was carried out by means of scanning electron microscopy coupled with chemical microanalysis by means of X-ray dispersive energy spectroscopy. The biocarbon obtained can be used as soil additions to increase the forests that surrond the University campus.

Biocarbon, prunning and gardening waste pirolisis, pilot plant

1. Introduction

According to Carvajal and Mera [1], in the last twenty years, the application of biofertilizers in Colombia has grown remarkably due to the wide demand for raw materials in industrial processes that use agricultural products, including the food industry.

Biofertilizers [2] are usually natural materials, such as fertilizers or decomposing
organic matter residues, which facilitate the restoration of the composition and structure of the degraded soil by regulating the pH, the incorporation of nutrients, the retention of humidity and recovery of soil texture.

Too biofertilizers based on cultures enriched with microorganisms are used directly, which are more used because of their ability to transform numerous chemical compounds into compounds available to plants [3]. Another possibility is the addition of carbonaceous material of plant or animal origin to the soil, such materials are known under the generic name of biocarbons [4]. The addition of biochar to the soil is widely used, since it is characterized by having among its main effects the mitigation of climate change by capturing C from the atmosphere [4]; improving soil fertility through increased water and nutrient retention [5]; the improvement of the microbial activity that, in turn, allows to increase the productivity of the crops [6]; and the increase of the soil surface [7]. Additionally, it is possible to regenerate the soil through the degradation of pollutants, recover waste (if biomass is used for this purpose) and produce energy (if it is recovered from the biochar production process) [8].

Pyrolysis has been defined as a thermochemical process that allows transforming low energy density biomass (and other organic materials) to high energy density liquids (bio-oils), solids of the same energy density (Biochar) or gases with low energy density (gas of synthesis) [11]. Involves heating organic materials to temperatures above 400 ºC in deficit or absence of oxygen. At such temperatures, thermal decomposition of the material used as a substrate occurs, allowing the release of vapors that, in turn, are cooled and recirculated, giving way to condensation of high molecular weight polar liquid compounds called biooils. While this occurs, low molecular weight volatile compounds (synthesis gases) remain in the gas phase, as do small amounts of hydrogen. These gases are used in industry, depending on the arrangement that you want to give it. A residual solid phase called biochar is also obtained, consisting of large amounts of carbon and other elements typical of the substrate, which can be used in aggregates to improve soil conditions [12].

2. Materials and Methods

For the present investigation, a discontinuous pyrolysis reactor (furnace) was built, which consists of two concentric chambers and partially isolated from each other, as shown in Figure 1. In the external chamber, or combustión chamber, it places as matter fuel the same plant residue that undergoes pyrolysis.

Figure 1. Chamber and gasifier of the pyrolysis system

Figure 2 shows the first pyrolysis system developed for preliminary tests, which contains the operation of the discontinuous reactor for pyrolysis of pruning residues. Figure 3 shows...
the complete pyrolysis system developed. The partial closure of the same guarantees a limited processing in oxygen, which guarantees the colatilization of the gaseous components present in the pruning residues. These volatiles exit through holes located in the lower part of the internal chamber and go into the external chamber, where they enter combustion along with the added fuel charge. Finally, by natural draft, the combustion gases are extracted from the system through the chimney.

The pruning and gardening residues, consisting of tree and shrub branches, leaves, grasses and sedes, came from the gardens of the campus of the University of Santander in Bucaramanga Colombia (see Figure 4).

Two samples of pruning and gardening residues, of different relative composition, were taken from the accumulations of plant material collected during the maintenance of the gardens. All the samples were subjected to the pyrolysis process for 2 hours, average time in which the external combustion process concluded with all the material used as fuel.

3. **Results and Discussion**

The next analysis, shown in Table 1, constitutes a group of gravimetric tests that help establish its main characteristics, particularly if you want to use it as a combustible substance.
Table 1. Results of the next analysis (Mass%) performed on the four biochar samples produced in this work

Table 2 shows the results of the last analysis of the two biocarbons obtained in the present study. This analysis shows the total percentages by weight of carbon, hydrogen and nitrogen of these materials. Simple 1, which had higher fixed carbon content, also showed higher total carbon contents. The observed difference between the percentage content of total carbon in Table 2 and the fixed carbon reported in Table 1, indicates the carbon fraction reported in Table 1, indicates the carbon fraction that is in the material that is associated with the remaining volatile fractions in the biochar, after pyrolysis of the initial biomass has taken place. It can be seen, then, that the biochar with the remaining volatile fractions in the biochar, after pyrolysis of the initial biomass has taken place. It can be seen, then the biochar with the highest, volatile carbon content is 2, which was derived from grass and dry leaf waste.

4. **Conclusion**

Significant variations were found, both morphological and physicochemical, depending on whether the pruning and gardening waste was composed mainly of Woody debris or grass and leaf litter. The biochar obtained from Woody waste (simple 1), presented higher percentages of fixed carbon and more appropriate characteristics for possible applications of fertilization of acidic soils with low water retention capacity. The biochar produced from litter and grass waste (simple 2), had a greater presence of ash stabilizing the soil aggregates (aluminosilicate type) and a greater amount of volatile matter (labile), which would make it applicable in remediation processes. Of soils affected by industrial – type activities. Further research will be conducted to effectively test these possible applications of both materials.
